Precision AC/DC Converters

Although semiconductor diodes available today are close to "ideal" devices, they have severe limitations in low level applications. Silicon diodes have a 0.6V threshold which must be overcome before appreciable conduction occurs. By placing the diode in the feedback loop of an operational amplifier, the threshold voltage is divided by the open loop gain of the amplifier. With the threshold virtually eliminated, it is possible to rectify millivolt signals.

Figure 1 shows the simplest configuration for eliminating diode threshold potential. If the voltage at the non-inverting input of the amplifier is positive, the output of the LM101A swings positive. When the amplifier output swings 0.6V positive, D1 becomes forward biased; and negative feedback through D1 forces the inverting input to follow the non-inverting input. Therefore, the circuit acts as a voltage follower for positive signals. When the input swings negative, the output swings negative and D1 is cut off. With D1 cut off no current flows in the load except the 30 nA bias current of the LM101A. The conduction threshold is very small since less than 100 µV change at the input will cause the output of the LM101A to swing from negative to positive.

A useful variation of this circuit is a precision clamp, as is shown in Figure 2. In this circuit the output is precisely clamped from going more positive than the reference voltage. When EIN is more positive than EREF, the LM101A functions as a summing amplifier with the feedback loop closed through D2. Neglecting offsets, negative feedback keeps the summing node, and therefore the output, within 100 µV of the voltage at the non-inverting input. When EIN is about 100 µV more negative than EREF, the output swings positive, reverse biasing D1. Since D1 now prevents negative feedback from controlling the voltage at the inverting input, no clamping action is obtained. On both of the circuits in Figures 1 and 2 an output clamp diode is added at pin 6 to help speed response. The clamp prevents the operational amplifier from saturating when D1 is reverse biased.

When D1 is reverse biased in either circuit, a large differential voltage may appear between the inputs of the LM101A. This is necessary for proper operation and does no damage since the LM101A is designed to withstand large input voltages. These circuits will not work with amplifiers protected with back to back diodes across the inputs. Diode protection conducts when the differential input voltage exceeds 0.6V and would connect the input and output together. Also, unprotected devices such as the LM709, are damaged by large differential input signals.

The circuits in Figures 1 and 2 are relatively slow. Since there is 100% feedback for positive input signals, it is necessary to use unity gain frequency compensation. Also, when D1 is reverse biased, the feedback loop around the amplifier is opened and the input stage saturates. Both of these conditions cause errors to appear when the input frequency exceeds 1.5 kHz. A high performance precision half wave rectifier is shown in Figure 3. This circuit will provide rectification with 1% accuracy at frequencies from dc to 100 kHz. Further, it is easy to extend the operation to full wave rectification for precision AC/DC converters.

![Figure 3: Fast Half Wave Rectifier](image3)
This precision rectifier functions somewhat differently from the circuit in Figure 1. The input signal is applied through $R_1$ to the summing node of an inverting operational amplifier. When the signal is negative, $D_1$ is forward biased and develops an output signal across $R_2$. As with any inverting amplifier, the gain is $R_2/R_1$. When the signal goes positive, $D_1$ is non-conducting and there is no output. However, a negative feedback path is provided by $D_2$. The path through $D_2$ reduces the negative output swing to $-0.7V$, and prevents the amplifier from saturating.

Since* the LM101A is used as an inverting amplifier, feedforward compensation can be used. Feedforward compensation improves the slew rate to $10 \text{V}/\mu\text{s}$ and reduces the gain error at high frequencies. This compensation allows the half wave rectifier to operate at higher frequencies than the previous circuits with no loss in accuracy.

The addition of a second amplifier converts the half wave rectifier to a full wave rectifier. As is shown in Figure 4, the half wave rectifier is connected to inverting amplifier $A_2$. $A_2$ sums the half wave rectified signal and the input signal to provide a full wave output. For negative input signals the output of $A_1$ is zero and no current flows through $R_5$. Neglecting for the moment $C_2$, the output of $A_2$ is $-\frac{R_7}{R_6} E_{in}$.

For positive input signals, $A_2$ sums the currents through $R_3$ and $R_6$, and

$$E_{out} = \frac{R_2}{R_3} E_{in} - \frac{R_7}{R_6} E_{in}.$$  

If $R_3$ is $\frac{1}{2} R_6$, the output is $\frac{R_2}{R_3} E_{in}$. Hence, the output is always the absolute value of the input.

Filtering, or averaging, to obtain a pure dc output is very easy to do. A capacitor, $C_2$, placed across $R_7$ rolls off the frequency response of $A_2$ to give an output equal to the average value of the input. The filter time constant is $R_7 C_2$, and must be much greater than the maximum period of the input signal. For the values given in Figure 4, the time constant is about 2.0 seconds. This converter has better than 1% conversion accuracy to above 100 kHz and less than 1% ripple at 20 Hz. The output is calibrated to read the rms value of a sine wave input.

As with any high frequency circuit some care must be taken during construction. Leads should be kept short to avoid stray capacitance and power supplies bypassed with 0.01 $\mu$F disc ceramic capacitors. Capacitive loading of the fast rectifier circuits must be less than 100 $pF$ or decoupling becomes necessary. The diodes should be reasonably fast and film type resistors used. Also, the amplifiers must have low bias currents.
